Abstract

Background

As the scale of genomic sequencing continues to grow, alignment-free methods for estimating sequence similarity have become critical for conducting tasks ranging from taxonomic classification to phylogenetic analysis on large-scale datasets [1,2]. The majority of alignment-free methods rely upon exact matching of k-mers: subsequences of length k, that can be counted and compared across datasets, with or without use of subsampling methods such as MinHash. As k-mer based methods rely on exact sequence matches, they can suffer from limited sensitivity when comparing highly polymorphic sequences or classifying organisms from groups that are not well represented in reference databases.

Current best practices methods can still only categorize a fraction of the metagenomic and metatranscriptomic data, especially for understudied and/or diverse habitats (xx% recovery for soil, xx% recovery ocean metagenomes, etc). Even well-studied environments such as human gut can produce significant uncharacterized metagenome content. “For example, a reference-based approach failed to map 35% of reads in the iHMP study on inflammatory bowel disease (Supp. Data. of (Franzosa et al., 2019)), omitting them from any further analysis. These reads may belong to unknown microbes, phage or viruses, plasmids, or accessory elements of known microbes, all of which can play a role in disease.[from RO1]”. This phenomenon is not restricted to metagenome samples. Alignment-based estimates can fail at larger evolutionary distances and even rRNA amplicon surveys may underestimate bacterial diversity [3].

To increase sensitivity of alignment-free methods, modified k-mer approaches have been introduced, including spaced seeds /split k-mers, which accommodate polymorphic sites in highly similar genomes (CITE). For larger evolutionary distances, protein-based comparisons have long been the gold-standard approach for taxonomic and functional annotation, as protein sequence is more conserved than the underlying DNA sequence [4,5]. As microbial and viral genomes are gene-dense, [MinHash-based] alignment-free comparisons of translated protein sequence have been shown to increase sensitivity for taxonomic classification and genome discovery [6,7]. Here, we demonstrate the utility of protein k-mer comparisons for phylogenomic reconstruction and taxonomic classification at larger evolutionary distances and across both gene-rich and [gene-sparse] sequences. We use Scaled Minhash subsampling to facilitate conducting these comparisons at scale [Irber et al., 2021; [8]/].

Scaled Minhash is a MinHash variant for selecting and hashing a set of representative k-mers from a sequence dataset [8/]. Unlike traditional MinHash, Scaled MinHash sketches scale with the size of the dataset, meaning each sketch is comprised of the chosen proportion of k-mers in the input dataset, rather than a chosen number of k-mers. Downsampling sequencing datasets in this way enables estimation of containment, which has been shown to permit more accurate estimation of genomic distance, particularly for genomes of very different lengths [9,10]. Streaming containment estimates have been shown to facilitate genome discovery and correlate with Mash Distance, a proxy for Average Nucleotide Identity (ANI) [7,11].

Standardized genomic measures of relatedness such as ANI and its protein counterpart, Average Amino Acid Identity (AAI) have shown lasting utility for genome relatedness and phylogenomic analysis. Traditional ANI and AAI describe the sequence similarity of all orthologous genes, either in nucleotide or protein space, respectively. Both been shown to be robust measure of overall pairwise genome relatedness even for highly incomplete datasets, such as those comprised of only ~4% of the genome or 100 genes [12,13]. ANI has emerged as the most widely-accepted method for estimating pairwise similarity of microbial genomes and delimiting species boundaries [14]. Recent research

appears to confirm 95% ANI species threshold for prokaryotic species, although there is some debate as to the universality of this threshold [15,16,17]. AAI thresholds have been proposed for higher taxonomic ranks, <45%, 45-65% and 65-95% for family, genus, and species [13,18]. While traditional alignment-based estimation of ANI and AAI are computationally intensive, sketching-based estimates and sketching-facilitated estimates have permitted ANI calculations at the scale of whole-databases [1,7,15].

[Pierce-Ward et al., 2021 (tbd technical paper)] showed that Scaled MinHash containment estimates can be used to approximate both ANI (nucleotide k-mers) and Average Amino Acid Identity (AAI; protein k-mers), while accounting for the non-independence of mutated k-mers [19]. Furthermore, Scaled MinHash containment estimates work well for genome pairs of varying lengths and for compositional analysis of metagenome samples. Taken together, these properties enable robust assembly and alignment-free pairwise relatedness estimation that can be used on sequences separated by a wide range of evolutionary distances. Here, we demonstrate that the utility of Scaled MinHash protein containment, both used directly and a an approximation of ANI and AAI, for taxonomic classification and phylogenomic reconstruction for species across the tree of life.

Results

K-mer analysis methods enable similarity detection as low as a single shared k-mer between divergent genomes. As a result, exact matching long nucleotide k-mers can be used for taxonomic classification and similarity detection between closely related genomes, including strain-level, species-level, and genus-level comparisons (often using k-mer lengths 51, 31, and 21, respectively). At larger evolutionary distances, accumulated nucleotide divergence limits the utility of exact nucleotide k-mer matching. Protein sequences, which are more conserved than their corresponding nucleotide sequences, are the gold standard for comparisons at larger evolutionary distances. Here, we evaluate the utility of amino acid k-mers for a wide range of genomic and metagenomic applications, including sequence distance estimation, taxonomic classification, and metagenome breakdown.

Amino Acid K-mer length selection

The Genome Taxonomy Database (GTDB) provides a genome-based taxonomy for bacterial and archaeal genomes [20]. We begin by assessing the prevalance of amino acid k-mers of different k-mer lengths within genomes (proteomes) selected for inclusion within GTDB. The most recent GTDB release, `rs202`, encompasses 258,407 genomes from 47,895 species.

To make analyses at this scale tractable, we built `sourmash` FracMinHash sketches, with a scaling factor of 1000 for nucleotide k-mers (keep ~1/1000 k-mers) and 200 for amino acid k-mers (keep ~1/200 protein k-mers) [21]. For most genomes, both genomic and protein fastas were available for download from NCBI. In remaining cases (n=36,632), genome fastas were translated into protein sequence via Prodigal [22] prior to sketching. We indexed these sketches into `sourmash` databases, which we have made available as part of the `Prepared Databases` section of the `sourmash` documentation, and archived on OSF [https://osf.io/t3fqa/] /Zenodo???.

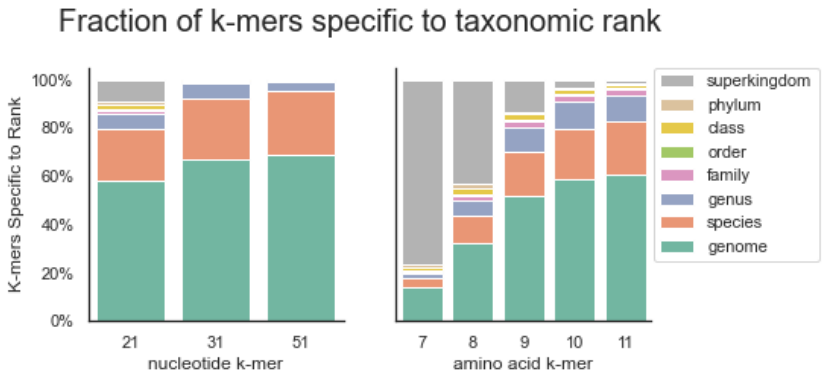

Figure 1: Fraction of k-mers specific to taxonomic rank For the GTDB-RS202 database, the majority of nucleotide k-mers are specific to (unique at) a specific genome, species, or genus. Few k-mers are shared across superkingdoms, though these do exist at k=21. K-mers shared at such a high level are indicative of high k-mer homoplasy: the presence of k-mers that are identical by chance rather than evolutionary descent.

For both nucleotide and amino acid k-mers, we first assessed the number of k-mers specific to each taxonomic rank: k-mers specific to a genome were only present in one genome in the entire database, k-mers specific to a species were found in at least two genomes of the same species, etc. K-mers specific to a "superkingdom" were found in genomes spanning at least two phyla. We assessed k-mer lengths ranging between k=7 and k=11, which roughly correspond to nucleotide k-mer lengths 21-31.

For all DNA k-mer sizes, the majority of k-mers are present in only a single species, with only a few k-mers shared across genera. Long nucleotide k-mers have already been shown to be useful for comparing genomes within the same genus or species. Only at a dna k-mer size of 21 are a significant fraction of k-mers present in genomes shared across different families or even phyla. In contrast, all protein k-mer sizes contain a portion of k-mers that are shared across genera and above. At a protein k-mer size of 7, over 80% of k-mers are present in genomes found in more than one phylum, while at a protein k-size of 10, the number of genome-specific k-mers is more similar to that observed for nucleotide k-mers.

Given the difference in k-mers found across taxonomic ranks, we decided to focus on amino acid k-mer lengths 7 and 10 for our primary analyses.

Abridged GTDB Test Dataset

While the GTDB database contains 258k genomes, many of these genomes are found within the same genus (e.g. 55k E coli genomes). To assess the utility of protein k-mers for comparisons at an array of evolutionary distances, we selected a subset of GTDB genomes that would allow standardized comparisons across taxonomic ranks, focusing on comparisons at the genus-level and above. For each genus with at least two species clusters in GTDB, one representative genome was randomly selected as an "anchor" genome. Then, one additional genome was selected from the GTDB representative genomes matching the anchor's taxonomy at each higher taxonomic rank. This "evolutionary path" consists of seven genomes: an anchor genome, a genome matching anchor taxonomy down to the genus level, one matching anchor taxonomy to the family level, one matching to the order level, and so on. This creates a gradient of similarity, where comparisons to the anchor genome range from genus-level to superkingdom-level.

Path selection using the representative genomes in GTDB rs202 resulted in 4095 paths comprised of 9213 unique genomes (8790 Bacteria, 333 Archaea). These paths include genome comparisons across 40 phyla (36 Bacteria, 4 Archaea), covering roughly a quarter of the 169 phyla (149 Bacteria, 20 Archaea) in GTDB release rs202. While paths are limited to taxonomies with at least two GTDB representative genomes for each taxonomic rank, these paths provide a rich resource for comparisons at increasing evolutionary distances.

Protein k-mers facilitate alignment-free comparisons at increased evolutionary distances

** FIGURE: containment/jaccard for evolpaths, DNA vs PROT THEN –> distance estimation?

genomes in same genus, fraction of k-mers in common at each ksize? ALL THE K-MERS

Accurate distance estimation from k-mer containment

all k-mers + scaled

Jaccard and Containment of DNA k-mers can be transformed into an estimate of the Average Nucleotide identity between genomes [cite Ondov Mash, Koslicki k-mer paper, koslicki scaled mh paper]. To begin with, we can apply the same equations to protein k-mer comparison statistics to obtain an estimate of Amino Acid Identity.

[Koslicki jaccard k-mer stats paper 23] showed how to properly transform Jaccard –> ANI assuming a simple mutational model. For protein k-mers, Jaccard/Containment can be transformed into Amino Acid Identity (AAI).

We can apply this same equation to protein k-mers

to do: A. redo with MRCC estimate; use only best graph (or maybe two ksizes)

talk with david: max containment? avg conainment? max containment? evolpaths = avg containment, whereas reference comparisonss –> avg containment

Containment enables comparison directly from DNA sequence

For protein k-mer comparisons to be useful, any DNA queries must be translated into protein sequence, either via assembly and translation or direct 6-frame translation. While assembly-based methods are more accurate, they often only work for a fraction of the available data. In contrast, 6-frame translation uses the entire dataset but generates a larger set of k-mers, only 1/6th of which are true protein k-mers. Here, the containment index is especially useful: by using only the containment estimate relative to the trusted reference proteomes, we can obtain accurate Amino Acid Identity estimates directly from DNA sequence. We term this “anchor” containment, where the trusted genome is the “anchor” upon which we base the comparison.

1. genome –> proteome (should be 100%, so not sure if worth?)
2. dataset a genome came from vs. that genome
3. sequencing from

** figure: AAI from translated nucleotide –> reference protein**

[reproduce equation? Scaled MinHash Koslicki] ** all k-mers; scaled minhash version [to do: run evolpaths with SCALED!]**

Robust Taxonomic classification from protein k-mer containment

Anchor containment can also be used to enable robust taxonomic classification from either protein or 6-frame translated DNA queries.

With experimental genomes where no reference taxonomic lineage is available, we assessed our annotation relative to `gtdb-tk` classification [24].

Taxonomic utilities are implemented in the `sourmash taxonomy` module.

- talk about full gtdb databases here?
- not sure if need them above so can do the rankinfo assessment?

Dataset	Exact Match	Higher Rank	Unclassified (sourmash)	Unclassified (GTDB-Tk)
MGNify-1000	95.7%	4.3%	N/A	N/A
Delmont-886	73.5%	26.5%	1 (0.1%)	15 (1.7%)

Metagenome breakdown using protein k-mers

Anchor containment also enables metagenome breakdown via min-set-cov.

Metagenome sequences can also be translated in 6-frames, and then the anchor containment can be assessed relative to proteomes in a reference database.

*** use a mock metagenome, then a evolutionarily distant metagenome. compare the % of genome recovred with DNA, protein at diff ksizes. Genome grist it, basically.

Discussion

K-mer based estimation of sequence identity has been limited to nucleotide sequences of similar size with high sequence identity (>80%),outside of which MinHash Jaccard is less well correlated with sequence identity [1,15].

By leveraging the Containment Index of Scaled MinHash sketches with both nucleotide and protein k-mers, we can extend accurate k-mer sequence identity to sequences of different sizes and to >50% Amino Acid Identity.

Cricuolo [25] (suggests w/ appropriate correction, nucl MinHash Jaccard can be used up to >65% ANI??)

Here, we utilize Scaled MinHash sketches with Containment to overcome size differences between sequences being compared.

To accurately estimate sequence identity from sequence files of different sizes(genomes, metagenomes, etc), we employ Scaled Minhash sketches, which enables estimation of the Containment Index.

A number of methods have used discriminatory k-mer analysis for taxonomic classification. However, most rely upon first developing a reference of discriminatory k-mers, e.g. k-mers unique to / diagnostic of a taxonomic group. Instead, sourmash gather leverages the Containment Index to find the reference match that shares the largest number of k-mers with the query sequence.

At k=21 (dna) and k=7 (protein), many k -mers are shared across taxonomic groups. Unlike many k-mer based classifiers, we do not need to explicitly characterize the discriminatory k-mers for each taxonomic group. The Containment Index uses all matched k-mers between the query and each reference, finding the % of each reference genome present in the query. Gather then selects the most covered (highest percent contained) reference genome, thus utilizing the combination of shared and discriminatory k-mers to find the most parsimonious match. After finding the best match, all matched k-mers are removed for the query in order to repeat the analysis to find the next most parsimonious genome match.

While this method is still dependent on a good set of reference genomes, updating the set of references with new data does not require recalculation of discriminatory k=mer sets...

** discussion of k-mer size **

- Scaled Minhash distance estimation is robust to completeness (unlike standard minhash https://drep.readthedocs.io/en/latest/choosing_parameters.html#importance-of-genome-completeness)

Conclusions

Containment-based pairwise distance estimation via Scaled Minhash enables accurate assembly-free and alignment-free phylogenomic reconstruction and taxonomic classification across a wide range of evolutionary distances.

Methods

Scaled MinHash Sketching with Sourmash

As implemented in sourmash [8,26,27], Scaled MinHash is a MinHash variant that uses a scaling factor to subsample the unique k-mers in the dataset to the chosen proportion (1/`scaled`). As k-mers are randomized prior to systematic subsampling, Scaled MinHash sketches are representative subsets that can be used for comparisons, as long as the k-mer size and chosen scaled value remain consistent. Unlike traditional MinHash sketches, Scaled MinHash sketches enable similarity estimation with containment, which permits more accurate estimation of genomic distance when genomes or datasets differ in size [9,10].

Sourmash v4.x supports sketching from either nucleotide or protein input sequence. All genome sequences were sketched with sourmash v4.0 using the `sourmash sketch dna` command, k-mer sizes of 21,31,51, a scaling factor of 1000. Sourmash also supports 6-frame translation of nucleotide sequence to amino acid sequence. To assess the utility of these translated sketches, genome sequences were also sketched with the `sourmash sketch translate` command at protein k-sizes (*kaa-mer sizes?*) of 7-12 and a scaling factor of 100. All proteome sequences were sketched with sourmash v4.0 using the `sourmash sketch protein` command at protein k-sizes (*kaa-mer sizes?*) of 7-12 and a scaling factor of 100. Where higher scaling factors were evaluated, these original sketches were downsampled using the sourmash `downsample` method prior to conducting sequence similarity comparisons.

Sequence Identity Estimation from Scaled MinHash

(very DRAFTy)

Sourmash contains standard implementations of Jaccard Index [1] and Containment Index [9] set comparisons.

Estimating Sequence Similarity from Jaccard For a comparison between two genomes (genomeA, genomeB), the Jaccard Index represents the k-mers shared between the two genomes (sketch intersection) divided by the k-mers present in both sketches (sketch union). Thus the Jaccard Index represents the percent of shared k-mers relative to all k-mers across both genomes (intersection/genomeA+genomeB). MinHash Sketch Jaccard has been shown to correlate well with ANI at high sequence identities (>=90% sequence identity) [1]; (>=80% sequence identity [15].

Mash Distance from Scaled MinHash Jaccard

TBD

Estimating Sequence Similarity from Containment As the Jaccard Index utilizes the union of all k-mers in a dataset, it is greatly affected by differences in dataset size [28]. The Containment Index instead represents the percent of a genome found in the comparison genome. Containment is directional: while the number of shared k-mers is fixed for a pairwise comparison, the Containment of each dataset will depend on the unique k-mers found in that particular dataset. Containment for genomeA will be (intersection/genomeA), while Containment for genomeB will be (intersection/genomeB).

Alignment-based ANI represents the sequence similarity of the alignable fraction of two genomes. In this way, ANI only compares the shared sequences, and discounts/ignores all other sequence present in either genome. Bidirectional containment comparisons use the same numerator (shared k-mers), but may contain different numbers of non-shared k-mers in the denominator.

In cases where both genomes are high-quality and highly complete, we can most closely approximate ANI by using the maximum value between the bidirectional containment values: that is, using the comparison that represents the shared sequence over the genome with the smallest number of non-shared k-mers.

In cases where one genome is more trusted (high quality and highly complete), Containment may be best calculated relative to the trusted genome. This use case also allows us to estimate sequence identity from larger sequence collections, such as metagenomes. By definition, metagenomes contain k-mers from many organisms. We can take advantage of directional Containment by calculating the Containment Index of Reference genomes that share many k-mers with the Metagenome. We have already shown the utility of Containment for metagenome classification [8], but now we can report estimated average sequence identity between the matching sequence regions and the reference genome.

Estimating Sequence Identity from Scaled MinHash

TBD

Blanca et al, 2021 [19] presented a method to estimate the mutation rate between MinHash sketches while accounting for the non-independence of mutated k-mers. Using [29], we estimate Sequence Identity from Scaled MinHash Containment.

Estimating sequence similarity from Scaled MinHash requires a good estimate of the number of unique k-mers in the sketched sequencing dataset [30]...

Scaled MinHash Distance Correlates with Standard Methods

FastANI v1.32 ([15]; run with default parameters) was used to obtain Average Nucleotide Identity between the anchor genome and each additional genome in its evolutionary path. FastANI is targeted at ANI values between 80%-100%, so only values in this range are considered "trusted" and used in **assessing the correlation between Scaled MinHash estimates and FastANI._(TBD)_**

CompareM v0.1.2 ([31]; run with `--sensitive` parameter for DIAMOND mapping) was used to obtain Average Amino Acid Identity between the anchor proteome and each additional proteome in its evolutionary path. CompareM reports the mean and standard deviation of AAI, as well as the fraction of orthologous genes upon which this estimate is based. Briefly, CompareM calls genes for each genome or proteome using PRODIGAL [5] and conducts reciprocal best-hit mapping via DIAMOND [22]. By default, CompareM requires at least 30% percent sequence identity and 70% percent alignment length to identify orthologous genes. As DIAMOND alignment-based homology identification may correlate less well with BLAST-based homology under 60% sequence identity [32/], **we also ran compareM with a percent sequence identity threshold of 60% to obtain a set of high-confidence orthologous genes for AAI estimation. We report correlation between Scaled MinHash AAI estimation and each of these compareM parameter sets in XX *(TBD)***. *CompareM was also used to obtain AAI values directly from each genome, using PRODIGAL to translate sequences prior to gene calling. These results [were not significantly different from proteome-based AAI estimation??] (Supplemental XX).*

Taxonomic Classification with Sourmash `Gather` and `Taxonomy`

To take advantage of the increased evolutionary distance comparisons offered by protein k-mers, we apply compositional analysis with sourmash gather [8] to protein sequences (amino acid input and 6-frame translation from nucleotides). Sourmash gather is conducted in two parts: First (preselection), gather searches the query against all reference genomes, building all genomes with matches into a smaller, in-memory database for use in step 2. Second (decomposition), gather does iterative best-containment decomposition, where query k-mers are iteratively assigned to the reference genome with best containment match. In this way, gather reports the minimal list of reference genomes that contain all of the k-mers that matched any reference in the database.

For reference matches with high sequence identity (ANI) to the query, we classify the query sequence as a member of the reference taxonomic group, as in [8]. **However, when ANI between the query and the top reference match exceeds the taxonomic rank threshold (e.g. species default 95%), we use a least/lowest common ancestor (LCA) approach to report likely taxonomy at a higher taxonomic rank *(TBD)***. Briefly, as gather reports non-overlapping genome matches, we can sum the k-mer matches for all genomes with shared taxonomies at the next higher taxonomic rank to report the best query containment at that rank. As this gather-LCA approach first uniquely assigns k-mers to their best reference genome, it bypasses the impact of increasing database size on taxonomic assignment observed for other LCA-based k-mer classification approaches [33].

Workflows and Computing Resources

Reproducible workflows associated with this paper are available at XX (gh link + doi for release), with datasets available at OSF (XX). All workflows were executed using snakemake >= 5.26 [34)] on the FARM cluster at UC Davis, using practices outlined in [35].

Luiz Irber, Phillip T Brooks, Taylor Reiter, NTessa Pierce-Ward, Mahmudur Rahman Hera, David Koslicki, CTitus Brown
Bioinformatics (2022-01-12) https://doi.org/gn34zt
DOI: 10.1101/2022.01.11.475838

22. **Prodigal: prokaryotic gene recognition and translation initiation site identification**
Doug Hyatt, Gwo-Liang Chen, Philip F LoCascio, Miriam L Land, Frank W Larimer, Loren J Hauser
BMC Bioinformatics (2010-12) https://doi.org/cktxnm
DOI: 10.1186/1471-2105-11-119 · PMID: 20211023 · PMCID: PMC2848648

23. **Debiasing FracMinHash and deriving confidence intervals for mutation rates across a wide range of evolutionary distances**
Mahmudur Rahman Hera, NTessa Pierce-Ward, David Koslicki
Bioinformatics (2022-01-12) https://doi.org/gn342h
DOI: 10.1101/2022.01.11.475870

24. **GTDB-Tk: a toolkit to classify genomes with the Genome Taxonomy Database**
Pierre-Alain Chaumeil, Aaron J Mussig, Philip Hugenholtz, Donovan H Parks
Bioinformatics (2019-11-15) https://doi.org/ggc9dd
DOI: 10.1093/bioinformatics/btz848 · PMID: 31730192 · PMCID: PMC7703759

25. **On the transformation of MinHash-based uncorrected distances into proper evolutionary distances for phylogenetic inference**
Alexis Criscuolo
F1000Research (2020-11-10) https://doi.org/gjn4jw
DOI: 10.12688/f1000research.26930.1 · PMID: 33335719 · PMCID: PMC7713896

26. **Large-scale sequence comparisons with sourmash**
NTessa Pierce, Luiz Irber, Taylor Reiter, Phillip Brooks, CTitus Brown
F1000Research (2019-07-04) https://doi.org/gf9v84
DOI: 10.12688/f1000research.19675.1 · PMID: 31508216 · PMCID: PMC6720031

27. **sourmash: a library for MinHash sketching of DNA**
C Titus Brown, Luiz Irber
The Journal of Open Source Software (2016-09-14) https://doi.org/ghdrk5
DOI: 10.21105/joss.00027

28. **Beware the Jaccard: the choice of similarity measure is important and non-trivial in genomic colocalisation analysis**
Stefania Salvatore, Knut Dagestad Rand, Ivar Grytten, Egil Ferkingstad, Diana Domanska, Lars Holden, Marius Gheorghe, Anthony Mathelier, Ingrid Glad, Geir Kjetil Sandve
Briefings in Bioinformatics (2020-09-25) https://doi.org/gjnvx4
DOI: 10.1093/bib/bbz083 · PMID: 31624847

29. **GitHub - KoslickiLab/mutation-rate-ci-calculator: This software calculates a confidence interval for the mutation rate from a set of observed containment indices under a simple nucleotide mutation process.**
GitHub
https://github.com/KoslickiLab/mutation-rate-ci-calculator

30. **[WIP] Ertl estimators for scaled minhash by luizirber · Pull Request #1270 · sourmash-bio/sourmash**
GitHub
https://github.com/sourmash-bio/sourmash/pull/1270

31. **GitHub - dparks1134/CompareM: A toolbox for comparative genomics.**
GitHub
https://github.com/dparks1134/CompareM

32. **AAI: BLAST vs Diamond**
LM Rodriguez-R
https://rodriguez-r.com/blog/aai-blast-vs-diamond/

33. **RefSeq database growth influences the accuracy of k-mer-based lowest common ancestor species identification**
Daniel J Nasko, Sergey Koren, Adam M Phillippy, Todd J Treangen
Genome Biology (2018-12) https://doi.org/ggc9db
DOI: 10.1186/s13059-018-1554-6 · PMID: 30373669 · PMCID: PMC6206640

34. **Sustainable data analysis with Snakemake**
Felix Mölder, Kim Philipp Jablonski, Brice Letcher, Michael B Hall, Christopher H Tomkins-Tinch, Vanessa Sochat, Jan Forster, Soohyun Lee, Sven O Twardziok, Alexander Kanitz, … Johannes Köster
F1000Research (2021-01-18) https://doi.org/gjjkwv
DOI: 10.12688/f1000research.29032.1 · PMID: 34035898 · PMCID: PMC8114187

35. **Streamlining data-intensive biology with workflow systems**
Taylor Reiter, Phillip T Brooks†, Luiz Irber†, Shannon EK Joslin†, Charles M Reid†, Camille Scott†, CTitus Brown, NTessa Pierce-Ward
GigaScience (2021-01-13) https://doi.org/gjfk22
DOI: 10.1093/gigascience/giaa140 · PMID: 33438730 · PMCID: PMC8631065
