Abstract

Background

As the scale of genomic sequencing continues to grow, alignment-free methods for estimating sequence similarity have become critical for conducting tasks ranging from taxonomic classification to phylogenetic analysis on large-scale datasets [1,2]. The majority of alignment-free methods rely upon exact matching of k-mers: subsequences of length k , that can be counted and compared across datasets, with or without use of subsampling methods such as MinHash [1] and derivatives such as FracMinHash [3]. As k-mer based methods rely on exact sequence matches, they can suffer from limited sensitivity when comparing highly polymorphic sequences or classifying organisms from groups that are not well represented in reference databases.

Current classification methods can still only categorize a fraction of the metagenomic and metatranscriptomic data, especially for understudied and/or diverse habitats (xx% recovery for soil, xx% recovery ocean metagenomes, etc). Even well-studied environments such as human gut can produce significant uncharacterized metagenome content. To increase sensitivity of alignment-free methods, modified k-mer approaches have been introduced, including spaced seeds /split k-mers, which accommodate polymorphic sites in highly similar genomes (CITE). For larger evolutionary distances, protein-based comparisons have long been the gold-standard approach for taxonomic and functional annotation, as protein sequence is more conserved than the underlying DNA sequence [4,5].

As microbial and viral genomes are gene-dense, [MinHash-based] alignment-free comparisons of translated protein sequence have already been shown to increase sensitivity for taxonomic classification and genome discovery [6,7]. Here, we demonstrate the utility of protein k-mer comparisons for both assembly-based and assembly-free metagenomic analyses. We use FracMinhash subsampling to facilitate conducting these comparisons at scale and increase accuracy relative to MinHash methods [3].

FracMinHash is a MinHash variant for selecting and hashing a set of representative k-mers from a sequence dataset [3]. Unlike traditional MinHash, FracMinHash sketches scale with the size of the dataset, meaning each sketch is comprised of the chosen fraction of k-mers in the input dataset, rather than a chosen number of k-mers. Downsampling sequencing datasets in this way enables estimation of containment, which has been shown to permit more accurate estimation of genomic distance, particularly for genomes of very different lengths [8,9]. Streaming containment estimates have been shown to facilitate genome discovery and correlate with Mash Distance, a proxy for Average Nucleotide Identity (ANI) [7,10].

Pairwise Overall Genome Relatedness indices (OGRI's) such as ANI and its protein counterpart, Average Amino Acid Identity (AAI) have shown lasting utility for genome relatedness and phylogenomic analysis. Traditional ANI and AAI describe the sequence similarity of all orthologous genes, either in nucleotide or protein space, respectively. Both have been shown to be robust measures of overall pairwise genome relatedness even for highly incomplete datasets, such as those comprised of only ~4% of the genome or 100 genes [11,12]. ANI has emerged as the most widely-accepted method for estimating pairwise similarity of microbial genomes and delimiting species boundaries [13]. AAI thresholds have been proposed for distinguishing higher taxonomic ranks, <45%, 45-65% and 65-95% for family, genus, and species respectively [12,14]. While traditional alignment-based estimation of ANI and AAI are computationally intensive, sketching-based estimates and sketching-facilitated estimates have permitted ANI calculations at the scale of whole-databases [1,7,15]. Hera et. al (2022) [16] introduced accurate nucleotide sequence distance estimation from

FracMinHash containment estimates, while accounting for the non-independence of mutated k-mers [17]. Here, we apply these approaches to protein k-mers for alignment-free AAI estimation.

For many mapping-based AAI approaches, it is important to report both the percent identity of matched regions and the fraction of the genomes that were mapped. This prevents believing artificially high similarity values when only small fractions of the genomes overlap. In contrast, containment-based AAI by necessity considers all of the sequence of at least one of the two genomes, as the containment measure is the matched k-mers divided by the total k-mers in the query genome. Since containment is directional, when both proteomes are equally trusted (e.g. neither set of protein k-mers is being 6-frame translated from genome sequence), then the average containment considers the entire set of protein sequence from both proteomes. While the AAI value is based on this measure, it may be useful to also consider/report the percent containment of each proteome alongside the AAI value, as this describes the percent of each proteome that matched.

Using these protein FracMinHashes with protein containment searches, we can conduct taxonomic classification on both assembled genomes and raw metagenome samples. The use of protein sequences increases sensitivity for finding sequence matches. For many classification methods, an increase in sensitivity is accompanied by a concomitant decrease in specificity, yielding large number of false positives, often even on mock communities [18,19]. Recently, a minimum metagenome cover approach has been developed using FracMinHash containment searches.

Here, we use this minimum set cover approach with protein FracMinHash to directly classify raw metagenome reads and to classify assembled genomes/proteomes..

Taxonomic Classification – current approaches + issues

..discuss min-set-cov /gather

BLASTX-style classification → proteins increase sensitivity. *notes:* - Kaiju[6] uses protein-level metagenomic classification using 6-frame translation, though Kaiju uses a seed-extend approach to generate protein alignments (minimum match length 11 aa), rather than a purely k-mer based approach. - sensitivity/specificity tradeoff – longer matches (minimum match length 11 instead of 12 for MEM yielded larger gains in sensitivity for a relatively small(er) loss in precision). - MEGAN-Prot (uses DIAMOND) [20] uses a BLASTX style approach - review incl. protein methods [21]

Here, we show that protein FracMinHash sketches can be used to find similarity across larger evolutionary distances than nucleotide k-mers. We demonstrate that FracMinHash Containment estimates can robustly estimate Average Amino Acid Identity across a range of evolutionary distances. We then use FracMinHash comparison methods to tackle two classification challenges: taxonomic classification of assembled genomes, and compositional analysis of metagenomes. Taken together, these results suggest that protein FracMinHash analyses can be used for metagenome sequence analysis, and may be particularly useful when sequenced organisms are more distantly related to organisms available in reference databases.

Results

K-mer analysis methods enable similarity detection as low as a single shared k-mer between divergent genomes. As a result, exact matching of long nucleotide k-mers can be used for taxonomic classification and similarity detection between closely related genomes, including strain-level, species-level, and genus-level comparisons (often using k-mer lengths 51, 31, and 21, respectively). At larger evolutionary distances, accumulated nucleotide divergence limits the utility of exact nucleotide k-mer matching. Protein sequences, which are more conserved than their corresponding nucleotide

sequences, are the gold standard for comparisons at larger evolutionary distances. Here, we evaluate the utility of amino acid k-mers for a wide range of genomic and metagenomic applications, including sequence distance estimation, taxonomic classification, and metagenome breakdown.

Amino Acid k-mers can be used to discriminate between taxa

The Genome Taxonomy Database (GTDB) provides a genome-based taxonomy for bacterial and archaeal genomes [22]. We begin by assessing the prevalence of nucleotide and amino acid k-mers of different k-mer lengths within assemblies selected for inclusion within GTDB. The most recent GTDB release, `rs202`, encompasses 258,407 genomes from 47,895 species.

To make analyses at this scale tractable, we built `sourmash` `FracMinHash` sketches, with a scaling factor of 1000 for nucleotide k-mers (keep ~1/1000 k-mers) and 200 for amino acid k-mers (keep ~1/200 protein k-mers) [3]. DNA `FracMinHash` sketches have been shown to accurately subsample genome datasets [3]. For most genomes, both genomic and protein fastas were available for download from NCBI. In remaining cases (n=36,632), genome fastas were translated into protein sequence via `Prodigal` [23] prior to sketching. We indexed these sketches into `sourmash` databases, which we have made available as part of the `Prepared Databases` section of the `sourmash` documentation, and archived on OSF [<https://osf.io/t3fqa/>] /Zenodo???

For a range of nucleotide and amino acid k-mers lengths, we assessed the fraction of k-mers specific to each taxonomic rank. For nucleotide k-mers, we used lengths of 21, 31, and 51, which are commonly used for analyses at the genus, species, and strain level, respectively. For amino acid k-mers, we focused on k-mer lengths ranging between k=7 and k=11, which roughly correspond to nucleotide k-mer lengths 21-31. K-mers specific to a genome were only present in a single genome in the database; k-mers specific to a species were found in at least two genomes of the same species, etc. K-mers specific to a superkingdom were found in genomes/proteomes from at least two phyla.

Fraction of k-mers specific to taxonomic rank

For the GTDB-RS202 database, the majority of nucleotide k-mers are specific to (unique at) a specific genome, species, or genus. Few k-mers are shared across superkingdoms, though these do exist at a k-mer length of 21. In contrast, all protein k-mer sizes contain a portion of k-mers that are shared across genera and above. At a protein k-mer size of 7, over 80% of k-mers are present in genomes found in more than one phylum, while at a protein k-size of 10, the number of genome-specific k-mers is closer to that observed for nucleotide k-mers. The differences observed between nucleotide and amino acid k-mers, as well as across different k-mer lengths suggests that these different k-mer sizes may provide resolution at different taxonomic ranks. We choose amino acid k-mer lengths 7 and 10 for our primary analyses, and have set a default kaa-mer length of 10 within `sourmash`.

Abridged Benchmarking Dataset

To rigorously assess the utility of protein k-mers for comparisons at an array of evolutionary distances, we selected a subset of GTDB genomes that would allow standardized comparisons across taxonomic ranks and overcome the database-inclusion limitations mentioned above.

For each genus with at least two species clusters in GTDB, one representative genome was randomly selected as an “anchor” genome. Then, one additional genome was selected from the GTDB representative genomes matching the anchor’s taxonomy at each higher taxonomic rank. This “evolutionary path” consists of seven genomes: an anchor genome, a genome matching anchor taxonomy down to the genus level, one matching anchor taxonomy to the family level, one matching to the order level, and so on. This creates a gradient of similarity, where comparisons to the anchor genome range from genus-level to superkingdom-level.

Path selection using the representative genomes in GTDB rs202 resulted in 4095 paths comprised of 9213 unique genomes (8790 Bacteria, 333 Archaea). These paths include genome comparisons across 40 phyla (36 Bacteria, 4 Archaea), covering roughly a quarter of the 169 phyla (149 Bacteria, 20 Archaea) in GTDB release rs202. While paths are limited to taxonomies with at least two GTDB representative genomes for each taxonomic rank, these paths provide a rich resource for comparisons at increasing evolutionary distances.

For DNA comparisons, each genome was sketched from the available genome downloaded from genbank. For protein comparisons, we conducted two comparison workflows. In both workflows, all anchor genomes were sketched from available proteomes (either downloaded or generated via Prodigal, as above). For the first workflow, comparison proteomes were also sketched from the available proteome. For these sketches, k-mer containment results are equally valid in both directions, so we report the mean containment for the comparison alongside the Jaccard Index. For the second workflow, comparison genomes were 6-frame translated to build protein FracMinHash sketches. As 6-frame translation introduces erroneous k-mers, we report only the containment estimate relative to the anchor proteome. We term this “anchor containment”, where the trusted genome is the “anchor” upon which we base the comparison. We conduct k-mer comparisons using FracMinHash sketches default fractional scaling: 1/1000 k-mers from DNA sketches and 1/200 k-mers for protein sketches (including 6-frame translated sketches). To verify results and estimate the impact of FracMinHash scaling, we also conduct comparisons using all available k-mers.

Protein k-mers facilitate alignment-free comparisons at increased evolutionary distances

We begin by assessing k-mer statistics across the 6 comparisons (each genome compared with the anchor genome) within each of 4095 evolutionary paths. When plotted by the rank of the lowest common ancestor, the dynamic range of containment values is much larger for protein k-mer comparisons. While DNA k-mers can provide resolution at the genus level, log-transformed containment values for protein k-mers continue to decrease, providing resolution for comparisons even between genomes of different phyla. Average containment estimated from proteome sequence is very similar to anchor containment estimated from 6-frame translation of genome sequence, suggesting that either value can be used for this type of comparison. We obtained similar results when comparing all available k-mers, suggesting that these results are not affected by FracMinHash scaling (*Supplemental Figure XX*).

To do: - add results from

6-frame translated sketches

Unique Amino acid k-mers correlate with proteome size

The number of unique amino acid k-mers is consistently correlated with the number of genes per

Distance estimation from FracMinHash sketch comparisons

DNA k-mer Jaccard has previously been used to estimate of the Average Nucleotide identity between genomes [cite Ondov Mash, Koslicki k-mer paper, Criscuolo?]. Recently, equations have been developed for FracMinHash Containment that estimate ANI while accounting for the nonindependence of mutated k-mers [16]. These equations assume a simple mutational model and estimate distance solely based on k-mer statistics. Here we apply FracMinHash distance estimation to protein k-mer comparisons to obtain an alignment-free estimate of Amino Acid Identity [16]. As above, we utilize anchor containment for comparisons involving 6-frame translated sketches.

To assess whether k-mer methods can be used to approximate AAI, we compared our results with alignment-based methods that leverage three different algorithms: EzAAIb (BLASTp), EzAAIm (MMSeqs2), and CompareM(DIAMOND). As BLAST-based alignment remains the gold-standard method, we compare all AAI values the BLAST AAI values.

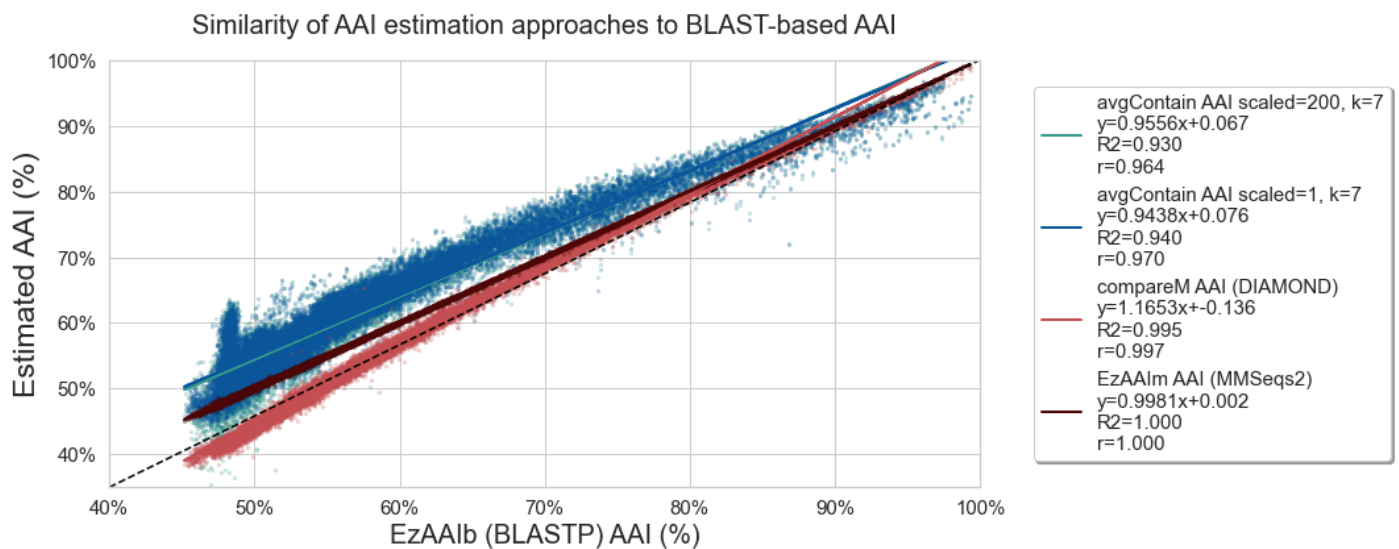

Figure 1: FracMinHash AAI vs BLASTP alignment based AAI

To do: - Rerun BLAST-AAI with default thresholds (current was lower identity thresholds) and re-plot - finish and add results from 6-frame translated sketches (anchor containment): same plot? or adjacent plot if needed.

Protein k-mer containment and AAI can be used for taxonomic classification

Given that protein k-mers facilitate similarity estimation across these larger evolutionary distances, we next assess the utility of protein k-mers for taxonomic assignment, both for metagenome breakdown/classification and for assembled genomes.

Metagenome breakdown using protein k-mers

As developed in Irber et al., 2022 [3], minimum set cover of nucleotide k-mers can be used to find the set of genomes that cover all known k-mers in a metagenome. This approach, implemented in `sourmash gather`, works by using k-mer containment relative to reference genomes ("anchor containment", as above) and "assigning" metagenome k-mers iteratively to the reference genome with highest containment. Anchor containment is then re-estimated using the remaining unassigned query k-mers until all known k-mers have been assigned. This step provides us with an ordered list of reference genomes, each of which represent a non-overlapping portion of the metagenome. The taxonomy of these matched reference genomes thus represents the closest match for each of these non-overlapping portions of the metagenome. In addition to reporting these exact matches, we can aggregate these taxonomic assignments of these matches to obtain taxonomic summarization at each rank.

Here, we assess the utility of protein k-mers for this application using the same metagenome samples described in Irber et al., 2022 [3]. As metagenome samples are unassembled, we use the 6-frame translation approach described above to obtain protein k-mers for comparison. No modification to the min-set-cov approach is required, as it already relies upon anchor containment to the reference genomes.

add figure: genome-grist mg breakdown, nucl k-mers, prot k-mers, nucl mapping

do we need an additional metagenome w/more divergent genomes, to show advantage of protein methods?

Robust taxonomic classification from protein k-mers

We use a similar approach for taxonomic classification of assembled genomes from protein k-mer containment. We apply the same minimum set cover approach to find the set of reference genomes that cover all known k-mers in our sample (in this case, a genome itself rather than a metagenome). If the most contained reference genome is sufficiently similar (passes default or user-defined threshold) to our query, we can annotate the query with taxonomic information from this reference genome. If not, we can use the genome-based lowest common ancestor approach to classify the query genome to the taxonomic rank where it contains sufficient similarity to matched reference genome sequence.

We select two sets of genomes: first, a set of 1000 genomes from the MGNify project ("MGNify-1000"), which are assembled from human gut and likely to be well-represented in existing databases. We next choose a set of 885 microbial ("Delmont-885"; 820 *Bacteria*, 65 *Archaea*) metagenome-assembled genomes (MAGs) assembled from TARA Oceans metagenomes [24]. As the marine environment is understudied relative to human gut, these genomes are more challenging for classifiers as they are less likely to have close relatives available in reference databases.

To assess the utility of protein k-mers for genome classification, we conduct this classification using three k-mer approaches: direct nucleotide k-mers, 6-frame translated protein k-mers, and direct protein k-mers from prodigal-translated proteomes. Where reference taxonomic lineages were available (MGNify-1000), we compared our results directly to these annotations. With experimental genomes where no reference taxonomic lineage is available, we assessed our annotation relative to `gtdb-tk` classification [25].

Dataset	Exact Match	Higher Rank	Unclassified (sourmash)	Unclassified (GTDB-Tk)
MGNify-1000	95.7%	4.3%	N/A	N/A
Delmont-885	73.5%	26.5%	1 (0.1%)	15 (1.7%)

to do: - discuss/utilize AAI threshold at all?

Notes

Include Jaccard → AAI results anywhere? - FracMinHash AAI values produced by Jaccard and Containment (here, average containment) methods are very similar.

Discussion

buyer beware: this is very much in notes/drafting form

Protein sequences are more conserved than their underlying DNA sequence, allowing protein k-mer comparisons to match across larger evolutionary distances. Protein sequence matching is also less impacted by sequencing errors due to codon degeneracy.

FracMinHash kaa-mer sketches support proteome analysis at scale

Our results show that amino acid k-mers can be used for global proteome analyses, including distance estimation (AAI) and taxonomic classification. For most microbial proteomes, systematic subsampling via FracMinHash maintains accuracy while enabling much faster comparisons.

Shorter amino acid k-mers (kaa = 7) can be matched even across phyla, suggesting they may be most useful for comparisons at larger evolutionary distances. These k-mers also have the potential to work well for functional analyses. Longer amino acid k-mers (kaa=10+) are more discriminatory and may be best for taxonomic classification.

kaa-mer Amino Acid Identity estimation

Kaa-mer estimation of Amino Acid Identity (AAI) correlates well with mapping-based AAI approaches, while requiring far less memory and computation. Different mapping approaches vary slightly in the AAI reported for a given pair of genomes, suggesting that comparisons are best made between values produced by the same method.

There is one other method that can function at large scale: MiGA webserver (paper has 11,000 pairwise comparisons) – and this method uses hAAI (heuristic AAI), only doing complete AAI if/when the hAAI cannot be estimated or is $\geq 90\%$ ("close to saturation"). MiGA "applies a hierarchical approach: hAAI, AAI, then ANI" to identify the best match genome/proteome.

Here we could envision doing this with protein k-mers → doing a quick high-scaled proteome search to find the right family, then doing a more detailed DNA/genome analysis.

Containment enables assembly-free protein comparisons

For protein k-mer comparisons to be useful, any DNA queries must be translated into protein sequence. This can limit amino acid comparisons to assembly-based workflows, as assemblies can be reliably translated into predicted Open Reading Frames (ORFs). By using only the k-mer containment estimate relative to reference proteomes, we can obtain accurate Amino Acid Identity estimates directly from DNA sequence. In this way, we can use the more permissive nature of protein analyses for assembly-free genome and metagenome assignment.

Taxonomic Assignment is database-dependent

(but protein helps with sensitivity + min-set-cov helps with specificity) discuss in relation to: Kaiju, CAT/BAT, MEGAN-prot, MMSeqs taxonomy (+ probably move some of this to intro)

K-mer based taxonomic assignment relies upon matching k-mers found in previously sequenced reference proteomes. While this approach will always be database-dependent and improved by presence of closely-related proteomes in the database, protein-based matching allows for classification at larger evolutionary distances. While protein matching increases the sensitivity by matching across synonymous substitutions in the DNA sequence

classification LCA approaches often suffer from sensitivity/specificity trade-offs Here, the use of `sourmash gather` minimum set cover approach assigns each protein k-mer to its most likely/parsimonious match based on presence of other proteome k-mers present in the query genome/metagenome.

distinguishing features this vs kaiju: - min-set-cov → low false pos - fracminhash → faster, smaller databases (though might need to increase scaled value) -

Limitations

- Note that comparing two 6-frame translated datasets is not recommended, as there is no mechanism to exclude erroneous k-mers introduced during translation.

- by using proteins, we're only looking at coding regions/ignoring noncoding (same as with all protein analyses)

Future directions and utility

- functional comparisons/all the k-mers
- abundance comparisons with cosine, f_unique_weighted, etc
- clustering at protein level
- While eukaryotic datasets are out of scope of this paper, these methods should work fine (except repeats/indels) – discuss a bit and/or do some analyses?

Using genomes from the Genome Taxonomy Database (GTDB) we develop showcase amino acid k-mer distributions across phyla and demonstrate taxonomic classification using sketch containment.

Protein search has long been used for comparisons conducted at increased evolutionary distances. By using amino acid FracMinHash sketches, we can make global protein similarity assessment tractable for the current scale of sequencing.

Main points: - Protein k-mers approximate proteomes - FracMinHash sketches can be used for global proteome comparisons - Longer protein k-mers can be used for taxonomic classification and metagenome breakdown - maximum containment enables these things directly from DNA sequence -

We expect sourmash protein k-mer analyses to be especially useful for species with few representatives in published databases.

Conclusions

Containment-based pairwise distance estimation via Scaled Minhash enables accurate assembly-free and alignment-free phylogenomic reconstruction and taxonomic classification across a wide range of evolutionary distances.

While here we have focused on demonstrating utility of amino acid k-mers for global proteome similarity, the correlation of unique amino acid 10-mers with genes should enable gene-level analyses, if sketching with sufficient k-mers.

Methods

Large-scale k-mer comparisons with FracMinHash sketches

FracMinHash sketching, as implemented in sourmash [3,26,27], is a MinHash variant that uses a scaling factor to subsample the unique k-mers in the dataset to the chosen fraction (1/ scaled). As k-mers are randomized prior to systematic subsampling, FracMinHash sketches are representative subsets that can be used for comparisons across datasets sketched with consistent k-mer lengths and scaling factors.

While FracMinHash sketches can be used to estimate both the Jaccard Index [1] and containment Index [8], containment has been shown to permit more accurate estimation of genomic distance when genomes or datasets differ in size [8,9,28,29]. We focus here on the utility of containment comparisons for similarity estimation. Containment comparisons are directional: the containment of genome A in sample B is the intersection of k-mers in A and B divided by the k-mers in genome A (and vice versa). Thus, two containment values can be estimated for a given pairwise comparison. The

choice of which containment value to use (or whether to average the two values) depends on the particular comparison. FracMinHash containment has been shown to be an unbiased estimator of the true containment index, as long as the sketches contain sufficient k-mers for comparison or utilize a high-quality estimation of the true cardinality of the dataset [3,16].

Sourmash supports sketching from either nucleotide or protein input sequence, to generate either nucleotide or protein FracMinHash sketches. We generated nucleotide and protein sketches directly from genome and protome files, respectively. All genome sequences were sketched with sourmash v4.2.1 using the `sourmash sketch dna` command, k-mer sizes of 21,31,51, a scaling factor of 1000. All proteome sequences were sketched with sourmash v4.2.1 using the `sourmash sketch protein` command at protein k-sizes (*kaa-mer sizes?*) of 7-12 and a scaling factor of 200. Sourmash also supports 6-frame translation of nucleotide sequence to amino acid sketches. To assess the utility of these translated sketches, genome sequences were also sketched with the `sourmash sketch translate` command at protein k-sizes (*kaa-mer sizes?*) of 7-12 and a scaling factor of 200.

In select cases, we also conducted comparisons using all available k-mers, rather than using FracMinHash sketch subsampling. While `sourmash` sketching is not optimized for this use case, we can generate these complete k-mer sketches using the same `sourmash` commands with a scaling factor of 1 (`scaled=1`).

Anchor Containment analysis for protein comparisons directly from DNA sequence

For protein k-mer comparisons to be useful, any DNA queries must be translated into protein sequence. This typically limits amino acid comparisons to assembly-based workflows, as assemblies can be reliably translated into predicted Open Reading Frames (ORFs). With k-mer methods, we can utilize direct 6-frame translation, which is assembly-free but does not attempt to find the correct open reading frame. Assuming a single open reading frame, only ~1/6th of the k-mers generated by 6-frame translation will belong to true ORFs. The remaining erroneous k-mers greatly impact the Jaccard Index (set similarity) when comparing samples, but only impact the containment index in one direction (relative to the 6-frame translated set). The containment estimate relative to reference proteomes will be an accurate comparison directly from DNA sequence. We term this “anchor” containment, where the trusted genome is the “anchor” upon which we base the comparison. Since 6-frame translation should always yield excess k-mers relative to genomes of similar size, this desired containment will generally be the larger of the two containment values (maximum containment).

To facilitate these comparisons within `sourmash`, we have implemented “maximum containment,” a shorthand method to select the greater of the two containment values. The maximum containment method may also provide advantages for genomes with potential contamination, as containment will always be relative to the smaller, and presumably less contaminated, genome. However, highly incomplete genomes may overestimate similarity with this method, so we suggest using containment relative to the more trusted sample if known, or considering both containment values when comparing two genomes of approximately equal quality. Note that comparing two 6-frame translated datasets is not recommended, as there is no mechanism to exclude erroneous k-mers introduced during translation.

Estimating Average Amino Acid Identity

MinHash Sketch Jaccard has been shown to correlate well with ANI at high sequence identities ($\geq 90\%$ sequence identity) [1]. Recently, Blanca et al, 2021 [17] presented a method to increase the accuracy of sequence similarity estimation from MinHash Jaccard by recognizing that k-mers generated from mutated sequence are not independent. Hera et al, 2022 [16] extended this approach to estimate

sequence identity from FracMinHash Containment estimates. Each of these methods assumes a simple mutational model, with equal substitution probability for each nucleotide, and then estimates sequence identity based on k-mer comparisons. Here, we note that there is nothing unique to nucleotide sequence included in these equations. By applying the same equations to comparisons between amino acid k-mer sketches, we can estimate average Amino Acid Identity (AAI) between proteomes. For this application, we maintain the assumption of a simple mutational model of equal substitution probability at each position, but recognize that it now applies to any amino acid, rather than any nucleotide. The equation for sequence similarity estimation (ANI or AAI) from FracMinHash Containment is reproduced here for completeness (see [16] for details).

to do: ADD EQUATION

Sequence distance estimation (ANI/AAI) is implemented in `sourmash` as of `v4.4`. The distance estimation equations can be found in the `distance_utils.py` file.

FracMinHash Amino Acid Identity Correlates with Alignment-based Methods

To assess whether k-mer methods can be used to approximate AAI, we ran generated alignment AAI values for each pairwise comparison using methods that leverage different mapping algorithms: EzAAIb (BLASTp), EzAAIm (MMSeqs2), and CompareM (DIAMOND). As BLAST-based alignment remains the gold-standard method, we compare all AAI values the BLAST AAI values.

EzAAI v1.12 [doi? 10.1007/s12275-021-1154-0] was used to run BLAST-based and MMSeqs-based Amino Acid Identity. The EzAAI workflow begins with PRODIGAL-based translation of genome sequence [5], followed by reciprocal BLAST [doi? 10.1016/S0022-2836(05)80360-2] or MMSeqs2 [30] alignment. For both, we utilized EzAAI default parameters: 40% coverage threshold, 40% sequence identity threshold. CompareM v0.1.2 ([31]; run with `--sensitive` parameter for DIAMOND mapping) was used to obtain Average Amino Acid Identity between the anchor proteome and each additional proteome in its evolutionary path. CompareM reports the mean and standard deviation of AAI, as well as the fraction of orthologous genes upon which this estimate is based. Briefly, CompareM calls genes for each genome or proteome using PRODIGAL [5] and conducts reciprocal best-hit mapping via DIAMOND [23]. By default, CompareM requires at least 30% percent sequence identity and 70% percent alignment length to identify orthologous genes. As DIAMOND alignment-based homology identification may correlate less well with BLAST-based homology under 60% sequence identity [32], **we also ran compareM with a percent sequence identity threshold of 60% to obtain a set of high-confidence orthologous genes for AAI estimation. We report correlation between FracMinHash AAI estimation and each of these compareM parameter sets in XX (TBD).** *CompareM was also used to obtain AAI values directly from each genome, using PRODIGAL to translate sequences prior to gene calling. These results [were not significantly different from proteome-based AAI estimation??] (Supplemental XX).*

Taxonomic Classification with Sourmash Gather and Taxonomy

To take advantage of the increased evolutionary distance comparisons offered by protein k-mers, we apply compositional analysis with `sourmash gather` [3] to protein sequences (amino acid input and 6-frame translation from nucleotides). `Sourmash gather` is conducted in two parts: first (preselection), `gather` searches the query against all reference genomes, building all genomes with matches into a smaller, in-memory database for use in step 2. Second (decomposition), `gather` does iterative best-containment decomposition, where query k-mers are iteratively assigned to the reference genome with best containment match. In this way, `gather` reports the minimal list of reference genomes that contain all of the k-mers that matched any reference in the database. For queries with high sequence

identity (ANI) to reference matches, we classify the query sequence as a member of the reference taxonomic group, as in [3]. However, when ANI between the query and the top reference match exceeds the taxonomic rank threshold (e.g. species default 95%), we use a least/lowest common ancestor (LCA) approach to report likely taxonomy at a higher taxonomic rank. Briefly, as gather reports non-overlapping genome matches, we can sum the k-mer matches for all genomes with shared taxonomies at the next higher taxonomic rank to report the best query containment at that rank. As this gather-LCA approach first uniquely assigns k-mers to their best reference genome, it bypasses the impact of increasing database size on taxonomic assignment observed for other LCA-based k-mer classification approaches [33].

These taxonomic utilities are implemented in the `sourmash taxonomy` module, and classifications were run on gather output via `sourmash tax genome`.

Workflows and Computing Resources

Reproducible workflows associated with this paper are available at <https://github.com/bluegenes/2022-protein-kmers-workflow> (ADD DOI for release), with datasets available at OSF (XX). All workflows were executed using snakemake ≥ 5.26 [34] on the FARM cluster at UC Davis, using practices outlined in [35].

Supplemental

Protein k-mers facilitate alignment-free comparisons at increased evolutionary distances

JACCARD: Protein k-mers are shared at higher taxonomic ranks Default scaled values 1000, 200

 Protein k-mers are shared at higher taxonomic ranks: ALL KMERS

Protein k-mers are shared at higher taxonomic ranks: ALL KMERS
